Abstract: This paper focuses on interpersonal dynamics between the child with disabilities and the adult monitoring his/her performance in Aesthetic Resonance Environments. Drawing upon a social constructivist approach, a framework for human interactivity was checked against empirical data obtained from the exploratory implementation of an environment intending to stimulate body awareness and enhance movement in a group of six children with severe neuromotor disabilities. The results showed that the adult assumed the role of a facilitator, mediating interactions between the children and the technological system. The provided social mediation increased the quality of movement and improved levels of engagement in the observed group of participants.

INTRODUCTION

The application of the concept of *aesthetic resonance* within the field of special needs and rehabilitation has been recently documented as a therapeutic tool of potential great value (1). The implementation of Aesthetically Resonant Environments is based on a core of technological resources that captures and transforms human physical movement in events that produce attractive changes in the proximal multi-sensory environment. Therefore, an Aesthetic Resonance Environment is generated by a responsive technology and according to Brooks et al (2, 205) refers to

"...a situation where the response to an intent is so immediate and aesthetically pleasing as to make one forget the physical movement (and often effort) involved in the conveying of the intention."

Such environments are in line with the key rehabilitation principle, which states that therapy must enable patients to improve their often residual capabilities without causing them unnecessary fatigue and frustration (3).

Aesthetically Resonant Environments are assumed to enhance movement through "fun" and aesthetic experience, hence implying a shift from task to play. Regarding the traditional views on rehabilitation, such shift is allowed in a context of non-human interactivity in which pleasurable experiences result from the interaction between the individual with disabilities and a (non-human) set of integrated digital devices. The formal role of human interactivity in this framework may become increasingly subsidiary as technological investment is made on individualizing the operating system according to the

functionalities, preferences, and needs of each user. Centered on optimizing the relation between the child with disabilities (C) and the system (S), research on Aesthetically Resonant Environments has paid little attention to the interpersonal dimension.

In Aesthetically Resonant Environments, however, interpersonal processes are inherent to the presence of an adult (A) monitoring the child's relation with the system. Even when we conceive the system as a stand-alone source of feedback, the intervention of the adult is likely to occur during CS (child-system) interactivity. Such intervention may simply show itself as the act of introducing the system to the child but may also extend to higher levels of involvement (e.g., demonstrating possibilities of gesture, encouraging responsiveness, improving child's performance through assistance and guidance). As Brooks (4, 89) contends,

"... even notionally single-user activities often happen together with other people and a purely virtual environment tends to cut people off from their surroundings making it difficult for several collocated people to share an experience. (...) For these reasons, purely virtual environments may not be desirable in cases where the participants have a disability".

As a general aim, our paper attempts to contribute to the expansion of a dyadic CS concept of Aesthetic Resonant Environments into a triadic CSA (child-system-adult) framework. Drawing upon the social constructivist view (5,6,7), we propose an approach using the adult as a mediator in the relation between the child with disabilities

and the responsive technological system. According to this perspective, child performance and interpersonal processes are not specifiable as independent entities. Taking "action in social context" as the unit of analysis requires a relational interpretation where the participation of the adult in shared activities is assumed to provide the necessary structure or scaffolding for the child to elaborate and transform his or her demonstrated skills (8).

The findings reported in the present paper came from a research project in which we designed and implemented an Aesthetically Resonant Environment intending to stimulate body awareness and improve the quality of movement in children with severe motor disabilities. As the interpersonal dimension appeared as an important organizer of children's behavior during the course of sessions, we decided to look closer at such dimension. Therefore, the more specific goal of this study was to investigate child-adult interactivity variables within the designed Aesthetically Resonant Environment. Did such interactivity affect children's performance? Did social interactive phenomena exert a strong influence on aspects like the quality of gesture or levels of child engagement in the observed sample?

METHODS

The participants were six children (three males and three females) with severe neuromotor disabilities associated with cognitive and language impairments. Their ages ranged from 12 to 13 years old and all were attending full-time (re)habilitation services in an institution for handicapped children. Inclusion criteria included the capacity to move upper limbs with a reasonable degree of amplitude, the ability to understand simple instructions (verbally or non-verbally), and to perceive contingencies between one's own gestures and the delivered visual/auditory feedback. Parents signed the informed consent.

Setup

Using a color tracking technique, a responsive digital system was designed that translated local gesture into visual and auditory feedback. Each tracked movement simultaneously generated visual feedback projected onto a screen and controlled the pitch variation of a MIDI instrument. Several templates were created, with different sorts of stimuli (e.g., notes from different scales versus chords versus percussive sounds). The choice of the program (timbre) was left as an option in the interface, as well as the possibility of shifting or lowering the register of each instrument.

The responsive system was implemented using the Max/MSP programming environment for audio processing components associated with the EyesWeb technology (www.eyesweb.org) for visual components. EyesWeb is an open software platform conceived for the multimodal analysis and processing of expressive gesture in movement.

Developed at the InfoMus Lab of the University of Genoa, the EyesWeb platform consists of a number of integrated hardware and software modules that can be easily interconnected and expanded. The software modules function as a development environment, including several libraries of reusable components, which can be assembled to build patches in a visual programming language.

Procedure and coding system

Each participant was observed during four sessions that took place on different days at the center where they were receiving (re)habilitation services. After entering the experimental room, the children were comfortably positioned, facing the screen on which visual feedback stimuli were projected. Sessions lasted approximately 25 minutes (Mean = 25 min. 30 sec; Range = 18 min. 20 sec. to 32 min. 10 sec.) and were videotaped using simultaneously two cameras placed at different points (one—the front camera—captured child's behaviors and the other—the back camera—taped screen events).

For analysis purposes, each session was divided into successive 10-seconds intervals, and the behavioral units were scored for their occurrence once (and only once) per interval, regardless of the number of onsets during the interval. Some units were recorded on an event base (the observer noted the presence or the absence of events but ignored their duration), and others were scored on a time base (an event was coded within a given 10-sec interval if it could at least be observed during most of the interval length).

All the event base units of the developed coding system apply to the child and are briefly described in Table 1. Full operational definitions, containing detailed behavioral descriptors and examples, are available from the first author.

Concerning time base units, the coding system assessed the children's engagement and the CSA interactivity. Engagement was broadly defined as the amount of time that the children spend interacting with the responsive technological system. Taking as reference the level of activity that each child was typically able to demonstrate, four levels of engagement behavior were considered:

- *Nonengaged*: The child is passive, unresponsive, and ignoring the adult or the visual/auditory information produced by the technological feedback system.
- *Attentional engagement*: The child is not actively interacting with the system but is paying attention to the adult while he or she interacts with the system.
- *Sparsely active engagement*: The child shows intermittent and non-sustained actions as if not fully interested in interacting with the system.
- *Active engagement*: The child actively interacts with the system performing continuously movements and attending to the delivered feedback.

Table 1. Brief definitions of event base observational categories

Categories	Definition
Non-verbal communication	Contextually appropriate use of conventionalized forms of non-verbal signs to express intentions, desires...
Verbal communication	Contextually appropriate use of recognizable words
Positive affect	Positive facial or vocal expressions (e.g., smiles, laughs)
Negative affect	Expressions of negative mood (facial, vocal or gestural)
Avoidance	Behavior (visual, postural) used to actively avoid contact or interaction with the adult
Spontaneous gesture	Gesture belonging to the child's typical repertoire performed without modeling by the adult
Imitative gesture	Gesture reproducing a gesture performed by the adult
Creative movement	Gesture involving elaboration of behavior (e.g., combinations, expansions) performed with an apparent creative intent

The CSA interactivity was described by the different interactional states abstracted from the child and/or the adult behavior. The following categories were defined:

- *Adult as model*: The adult is mainly directive while demonstrating the system to the child. Demonstrative movements may just involve actions performed in front of the child, or may include physical contact (e.g., adult manipulates the child's hand to obtain feedback from the system). Verbal instructions are also coded in this category.
- *Child-Adult as peers in the system*: Both adult and child interact simultaneously with the system by reciprocally imitating or elaborating each other behavior (e.g., combinations; expansions). Although non-directive, the adult may take some initiatives, providing props, comments on the child's actions or suggestions to extend the child's activity.
- *Child-Adult as peers outside the system*: Child-adult interactions with no direct intermediation of the technological responsive system (e.g., child engages in play or in direct communication with the adult, "ignoring" the system).
- *Child as performer/Adult as public*: The child spontaneously uses the system with the noticeable purpose of being observed and appreciated by the adult. (e.g., before, after or while interacting with the system the child looks at the adult as if waiting for approval or for some other kind of reinforcement).
- *No social interaction*: When no one of the previous described categories is observed (e.g., the child ignores the adult; the adult is controlling the technological device not paying attention to the child).

In observational research, a principal index of usefulness is the reliability of the used coding system, as measured by interobserver agreement. To establish the reliability of obtained scores, two independent observers coded a total of 120 minutes of the tapes (i.e., 720 10-sec intervals). Reliability was determined for event base categories (as a whole), for engagement behavior and for Child-System-Adult interactivity, and was computed as the total number of agreements divided by the number of agreements plus disagreements. The levels of reliability were 83% for event base categories, 88% for engagement behavior, and 85% for CSA interactivity.

Data analysis

Because of the variations in the number of observed intervals, the results are described in terms of relative frequencies (RFs). The RFs were calculated by dividing individual frequencies by the total amount of intervals considered in each unit of analysis. To examine the statistical significance of differences, we used non-parametric tests. In these tests, the original scores are changed from continuous to ordinal scales. As usually recommended in such cases, group results for the dependent variables will not be presented through means but rather described by their median values.

RESULTS

The RFs medians for the coded interactive states in each of the four sessions are presented in Table 2. As the results from the Friedman two-way analysis of variance test revealed, the lengths of *No Social Interaction* and of *Adult as Model* states decreased significantly from session to session. Inversely, there was a significant trend for the occurrence of the other three interactive states to augment across sessions.

Child engagement and child-system-adult interactivity

Considering each interactive state as a separate unit of analysis, we could verify that, when there was no ongoing social interaction between the child and the adult, instances of the *nonengaged* category were clearly predominant (RFs median = .888). Within this interactive state, a few instances of *active engagement* (RFs median = .066) and of *sparsely active engagement* (RFs median = .035) levels could be observed. The Wilcoxon matched pairs signed ranks test

Table 2. RFs medians for interactive states in the four sessions

Interactive State	Session				Significance
	First	Second	Third	Fourth	
No social interaction	.218	.139	.117	.065	$p < .001$
Adult as model	.356	.313	.154	.110	$p < .001$
CA as peers in the system	.108	.173	.229	.252	$p < .001$
CA as peers outside the system	.077	.096	.155	.220	$p < .001$
C as performer/A as public	.253	.241	.302	.348	$p < .003$

showed that differences between the first (nonengaged) and the other two distributions (active and sparsely active) were significant ($Z = -2.20$; $p < .03$).

Only two levels of engagement occurred during the 'adult as model' interactive state: the *attentional engagement* (RFs median = .682) and the *nonengaged* (RFs median = .318). Compared with the second, the first level has appeared with higher incidence in all six participants. Such predominance reached statistical significance, as indicated by a two-tailed sign test ($p < .04$).

Concerning *Child-Adult as peers in the system*, there was a clear prevalence ($p < .04$; two-tailed sign test) of the *active engagement* level (RFs median = .902) as compared with the *sparsely active engagement* one (RFs median = .099). During this state, no instances of the *nonengaged* and of the *attentional engagement* levels were registered. Whereas *Child as performer/Adult as public* was an ongoing state, *active engagement* (RFs median = .872) appeared more frequently than the *sparsely engagement* (RFs median = .149) level did. Because the opposite trend was observed in one of the six participants (RF for active engagement = .423; RF for sparsely active engagement = .577), the difference did not reach statistical significance ($p > .217$; two-tailed sign test). Because we defined engage-

ment as the amount of time children spend inter-acting with the system, no engagement behavior was coded during the so-called state *Child-Adult as peers outside the system' state*.

Quality of movement and Child-System-Adult Interactivity

The incidence of spontaneous gestures (RFs median = .897) was higher than were the incidences of imitative gestures (RFs median = .071) and of creative movements (RFs median = .033). To explore the possible relations between the quality of movement and CSA interactivity, we considered the total amount of time intervals assigned to the category of *creative movement*. Proportional occurrences were, then, calculated taking into account the following interactive states: (A) *no social interaction*, (B) *adult as model*, (C) *child as performer/adult as public*, and (D) *child-adult as peers in the system* (as CS interactivity could not be observed in *child-adult as peers outside the system*, we ignored this state). The same procedure was followed for the categories of *imitative gesture* and *spontaneous gesture*.

Most instances of *creative movement* appeared while the child and the adult were playing *as peers in the system* (see Figure 1).

Fig. 1: Medians (RFs) for creative movements, imitative gestures, and spontaneous gestures as function of the considered interactive states

Imitative gestures were more frequent within *child as performer/adult as public* and *child-adult as peers in the system* than within time segments when *no social interaction* or *adult as model* were observed ($p < .04$; two-tailed sign test). Differences concerning spontaneous gestures between the first, the third and the fourth interactive state were not statistically significant.

Affect expressions and Child-System-Adult Interactivity

The time intervals assigned to each of the interactive states were the measures (units of analysis) from which the RFs for 'positive affect', 'negative affect', and 'avoidance' have been extracted. Avoidant behavior was rarely observed. Only three children expressed few instances of avoidance while the adult was acting as a model. Expressions of negative affect were also seldom observed and merely occurred during the following two interactive states: *no social interaction* and *adult as model*.

Concerning the occurrence of positive affect, instances appeared in the states of *adult as model* (RFs median = .290), *child as performer/adult as public* (RFs median = .148), *child-adult as peers in the system* (RFs median = .464), and of *child-adult as peers outside the system* (RFs median = .571).

The Friedman two-way analysis of variance test indicated that the differences were overall statistically significant ($p < .006$). Pairwise comparisons by the Wilcoxon test revealed that incidences of positive affect differed between the states of *child-adult as peers in the system* and of *adult as model* ($Z = -1.99$; $p < .05$), as well as between *child-adult as peers in the system* and *child as performer/adult as public* ($Z = -2.20$; $p < .03$). The latter two distributions (*adult as model* and *child as performer*) also differed significantly from the distribution within the

state of *child-adult as peers outside the system* ($Z = 1.99$; $p < .05$ and $Z = -2.20$; $p < .03$, respectively). The differences between events assigned to the states of *child-adult as peers in the system* and *outside the system* did not reach statistical significance ($p > .11$).

Communication and Child-System-Adult Interactivity

Considering the total amount of time intervals assigned to the categories of 'non-verbal communication' and of 'verbal communication' as the unit of analysis, we explored the relations between communicative behavior and CSA interactivity. One participant revealed instances of verbal and non-verbal communication in most of the interactive states. The other participants demonstrated these behaviors only during the states of *child-adult as peers* (in or outside the system). Both verbal and non-verbal communication behaviors were more frequent in the interactive state of *adult-child as peers outside the system* than in the other referred state (Figure 2).

Concerning non-verbal and verbal communication, the differences between occurrences in both interactive states were significant ($p < .04$; two-tailed sign test).

DISCUSSION

The research base for providing (re)habilitation services to children with disabilities has evolved dramatically in the past few years. More complete and detailed information about how humans learn and develop is available now. Contemporary views stress that development occurs across multiple interconnected behavioral levels (9,10), and several integrative approaches describe how the social relationships of children with adults and peers provide the critical foundations for learning and development (11).

Fig. 2. Medians (RFs) for non-verbal and verbal communication behaviors as function of the considered interactive states.

The recognition that social contexts exert a strong influence on child behavior led us to explore the interpersonal dynamics between children with severe neuromotor disabilities and the adult monitoring their performance in a multi-sensorial Aesthetic Resonance Environment. The results showed that adult-child interactions provided an organizing structure for children activities.

Child engagement and expressions of positive affect increased while children and the adult were participating in shared activities, namely when they were acting *as peers inside the system*. This interactive state seemed to make visual modeling more efficient, affording the necessary scaffolding for the child to 'reinvent' own gestures and to transform them into creative movements. A specific form of modelling—a scenario in which the adult suggests trajectories by moving his/her hand over the screen—appeared as a particularly powerful technique to catalyze subsequent new gestures. Both imitative and creative movements were evoked when the child seemed to act *as a performer in front of the adult*. Furthermore, instances of verbal communication were observed mainly when the child and the adult related with each other *as peers outside the system*. On the other side, if the adult was demonstrating the system, then the children were likely to remain quiet and 'attentively engaged'.

The analysis revealed that joint-activities increased from the first to the fourth observation. A trend was indeed found for instances of *child/adult as peers* (inside or outside the system) to emerge more frequently across sessions. Even though the adult used some facilitation strategies to initiate and maintain the occurrence of such interactional states, the portrayed results are likely to reflect the effects of practice and learning. The children acquired a progressive capacity to handle the system. Because social behavior is fuelled by feelings of efficacy following self-recognized achievement of mastery (12), the enhanced sense of control may have encouraged them to participate in child-adult shared activities.

Specific and new intervention perspectives are revealed when the interpersonal dimension within Aesthetically Resonant Environments is explored. Recognizing the importance of such dimension underscores the potential advantages of integrating social mediation procedures in (re)habilitation frameworks inspired on the concept of 'aesthetic resonance'.

Disabilities can lead to general developmental problems that become increasingly greater as individuals grow older. Regarding neuromotor-disabled children, the evidence shows that most of them do not easily engage in social interactions with others (13). Subsequent delays in the social and communicative domains are, in turn, likely to reduce the children's ability to learn from social environments (14). The detrimental impact of such disability-amplifying processes can be minimized if interpersonal phenomena that seem to be unique to CSA interactivity are assessed and targeted as intervention goals. Likewise, the same processes

that frame social behavior as a relevant factor in neuromotor (re)habilitation should be seen as possible tools for intervention in other kinds of disabilities—namely in those where social behavior is itself the primary target (e.g., autistic spectrum disorders).

Practices of embedding interpersonal dynamics in CS interactivity call for more research and further refinements. We are currently conducting an investigation on facilitation strategies to enhance adult-child interactions. Conceptually guided by principles from the 'Zone of Proximal Development' construct (15), this work aims at the elaboration of guidelines to improve quality of CSA interactivity within Aesthetically Resonant Environments.

ACKNOWLEDGMENTS

Thanks to Carlos Araujo for his expertise in preparing digital versions of the videos. Thanks to the participants and their parents for their unconditional willingness to collaborate in this study. Thanks to the Rehabilitation Center "Rui Abrunhosa" and their staff for the provided collaboration.
